Perceived Risk of HIV Infection and Mental Well-being in Rural Malawi

Introduction

Previous studies have shown that people living with HIV/AIDS have worse mental health than HIV-negative people both in developed and developing contexts. However, little is known about how an individual's perceived risk of HIV infection may also influence his mental health outcomes, where the actual HIV status is held constant. In an HIV epidemic, where AIDS is a common cause of death in one's social network, lower mental well-being becomes a public health issue. Individuals may be continuously worried about being infected and may also be grasping the loss of family members. Additionally, perceived HIV/AIDS stigma in the local community may further deteriorate one's mental well-being. At the same time, social support is expected to ameliorate these negative impacts. The purpose of this research is to examine the relationship between the issues related to HIV risk perception and mental well-being.

Methods

Fixed-effects approach is used to determine whether change in the perceived risk of HIV infection predicts change in the level of mental well-being over time. Models are estimated separately by gender and take the form:

\[ \text{MCS-12}_\text{i, t} = \beta_0 + \beta_1 \text{ perceived risk}_\text{i} + \beta_2 \text{ social support}_\text{i} + \beta_3 \text{ X}_\text{i} + \beta_4 \text{ (perceived risk x social support)} + \epsilon_\text{i, t} \]

where \( \text{X} \) is a vector of individual time-varying characteristics by individual i at time t (e.g., a vector of unobserved fixed factors that determine MCS-12). Since stigma is only observed in 2006, the model cannot estimate its main effects.

Results

Fixed-effects Linear Regression of Mental Component Scale (MCS-12) on HIV Risk Perception, Women in Rural Malawi

Conclusions

The perceived risk of HIV infection has a significant negative relationship with MCS-12 in rural Malawi. This indicates that not only actual but also perceived HIV infection predicts mental health status.

Although religious participation may boost mental well-being for women, social support in general does not ameliorate the negative association between risk perception and MCS-12. This corresponds to the fact that Malawians have recognized that many cases of infection are not due to sexual infidelity and promiscuity in the epidemic (e.g., faithfulness, spouses and children). The infection cannot always be accounted for by individual moral responsibility. Therefore, the stigma (specific to sexual behavioral) in the community may not generate discriminative effects and mental burden.

Limitations

This research might benefit from other social support measures that directly indicate the content and quality of support, such as having confidants to discuss HIV/AIDS concerns. In addition, testing the relationship between HIV risk perception and other mental well-being measures (such as depression and anxiety) will improve our understanding of the domains of mental health that are more seriously affected.
